

## AdiIRC - \$~ - # 2

*Added in 1.9.2*

### **\$~[identifier]**

A identifier prefixed with "~" executes normally if the identifier exists, and otherwise returns \$null without generating a missing identifier warning if that's enabled. This also ensures that it cannot execute a custom alias of that same name.

```
//echo -a $ticksqpc and $~ticksqpc
```

In this example, the 1st \$ticksqpc executes the built-in identifier if the script runs in a version new enough to contain that identifier. In older versions, it could execute a custom alias if it exists as that name, and otherwise would either return \$null or trigger the optional identifier warning.

The 2nd \$~ticksqpc never executes a a custom alias, and either executes a built-in identifier existing by that name, or in too-old versions returns \$null without triggering the optional identifier warning.
